Shoreline detection

SPOT-5 image

ABSTRACT

Recently, many researchers have directed their attention to methods of predicting shorelines by the use of multispectral images. Thus, a simple and optimised method using image enhancements is proposed to improve the low contrast of the Satellite pour l'Observation de la Terre-5 (SPOT-5) images in the detection of shorelines. The near-infrared (NIR) channel is important in this study to ensure the contrast of the vegetated area and sea classification, due to the high reflectance of leaves in the near infrared wavelength region. This study used five scenes of interest to show the different results in shoreline detection. The results demonstrated that the proposed method performed in an enhanced manner as compared to current methods when dealing with the low contrast ratio of SPOT-5 images. As a result, by utilising the near-infrared histogram equalization (NIR-HE), the contrast of all datasets was efficiently restored, producing a higher efficiency in edge detection, and achieving higher overall accuracy. The improved filtering method showed significantly better shoreline detection results than the other filter methods. It was concluded that this method would be useful for detecting and monitoring the shoreline edge in Tanjung Piai.

1. INTRODUCTION

Shoreline delineation is difficult, time-consuming, and sometimes impossible for the entire coastal system when using traditional ground surveying techniques [1]–[5]. Consequently, in satellite images, there is a need to overcome the difficulties in the extraction of shorelines [3]–[21]. Many computational methods are yet to be improved, and comprehensive methodologies are needed to be developed to extract the complex properties of multi-features in satellite images [2], [6], [22]–[34]. The challenges of shoreline detection are faced during the extraction of dense area features, when the satellite images suffer from surface reflectance during data acquisition [2], [4], [5], [22], [31], [32], [35], [36]. The current methods are discussed to analyse the limitations that occur during shoreline detection. There are several objectives explained, which indicate as to why this research is being conducted to notify the importance of accomplishing the goal. Furthermore, Satellite pour l'Observation de la Terre-5 (SPOT-5) images are used throughout this study by utilizing the

pan-sharpened image with a combination of the false color composites which consist of near-infrared (NIR), red, and green channels. Subsequently, the contrasts of the SPOT-5 images are improved by integrating the near infrared histogram equalization (NIR-HE) method for features preservation and edge detection [23], [33], [37]–[40].

An image captured in bad weather often yields low contrast results, due to persistent cloud cover and haziness, which attenuates scene radiance [23], [41]. Hence, electromagnetic energy is unable to reach the sensor before it passes through a substantial atmospheric scene [23], [42]. Hazy days in Malaysia are most likely to occur from January to February and from June to August [43], [44]. Haze is the appearance of atmospheric absorption and scattering of gases. The particles that cause the hazy appearance may originate from many sources, some of which are natural sources and some of which are anthropogenic sources [45]–[47]. Natural sources include the oceans, forests and the ground surface. However, a majority of the particulates originate from human activities such as open burning, land clearing and the combustion of fossil fuels in industrial boilers. Images taken with surface reflectance conditions will be affected by the low contrast [42]. Therefore, misclassification of features may occur due to low contrast. The efficiency of the haze removal method to remove haze is probably not quite as sufficient as the multispectral data applied, which is meant for retrieving features in the incorrect classes.

Moreover, imagery with the presence of surface reflectance is prone to have weak edges, poor visibility, and misclassified pixels [46]–[50]. As a result, this would produce inefficient extraction of multiclasss, which causes missing line cues and a mixture of features. In order to produce a prediction of shoreline changes, the second challenge is to cater, which is to improve the filtering method by sharpening the image boundaries and eliminating the problem of misclassified pixels of the shoreline. Unfortunately, the prediction of shorelines is often poor because of inaccurate features due to misclassification. The images may lose image information [51]. As a consequence, an improved filtering method is essential for drawing more reliable edges for shorelines, with a high accuracy of features classification. These would eventually produce clear recognition and extraction of shorelines [2], [4], [22], [32], [35]. Additionally, for each application and image, a custom image enhancement method, and an adjustment of contrast while preserving the edges are usually necessary.

The goal of NIR-HE using the NIR channel is to improve the image contrast and hence to make it suitable for classification of vegetation in feature extraction [2], [28], [33], [38], [40], [48], [52]–[55]. The false color composite image is enhanced using HE algorithm. The range of brightness values presented in an image is referred to as a contrast. Thus, the contrast is enhanced efficiently by using HE in a SPOT-5 image. An advantage of this method is that it manipulates the NIR channel, green channel and red channel [56]–[67]. By utilizing the NIR channel, it is important to note that the deep penetration of its long wavelength makes it possible to unveil the details of vegetation that could otherwise be lost entirely [49], [53], [62], [68]–[70]. The purpose of the NIR-HE method is to improve the low contrast of an image caused by surface reflectance issues. This paper is composed of several sections. Section 2 discusses research method on image enhancement, pan-sharpening, integrating NIR channel and image classification. Section 3 explains the analysis of the image enhancement method and analysis of feature signatures. The conclusions and recommendations for future work are presented in section 4.

2. RESEARCH METHOD

2.1. Image enhancement

Many researchers in recent years have focused on images taken in bad weather, which often produce low contrast results due to the presence of surface reflectance in the atmosphere, which reduces scene radiance [71]. In the process of image enhancement, the noise will be removed from the images, and the image contrast will be enhanced. Low contrast images with weak edges pose challenges in the fields of computer vision and pattern recognition [72]. However, the all year round tropical hot and humid climate in Malaysia is also a challenging problem because of the relevance between the persistent cloud covers and hazy days. Removing the noises can increase the visibility of the scene, correcting the color shift affected by the air light [73].

Images with surface reflectance conditions will reduce visibility, and low contrast images reduce the performance of various image processing and computer vision techniques [41]. The dehazing method is a standard technique to remove surface reflectance and ensure high image visibility, as well as to correct the color shift caused by the air light [74]. The image with the presence of surface reflectance issues is prone to have biased low contrast scene radiance. However, haze removal has been a challenging issue where the hazy situation is dependent on unknown depth information [74]. According to [75], the original details of images need to be preserved, even though the visibility of an image has been improved. Many approaches have been proposed for addressing the problem of surface reflectance condition such as hazy and cloudy conditions.

These approaches are categorized into two types: multiple image processing or additional information methods [76]–[79], and single image processing approaches [29], [42], [43], [73], [80]–[82]. Therefore, a comprehensive study to improve the surface reflectance problem while maintaining detailed information on an image is highly recommended.

2.2. Pan-sharpening of SPOT-5 images

As depicted in Figure 1, pan-sharpening was used to increase the spatial resolution, and to provide better visualization of a multiband image, using a lower-resolution and single-band image [83]–[86]. Pan-sharpening is the process of merging multispectral and panchromatic imagery, thereby creating a single high-resolution colour image. A panchromatic image contains only one wide channel of reflectance data. Modern multispectral scanners also generally include some radiation at slightly longer wavelengths than red light, called near infrared. Panchromatic images can be generally collected with a higher spatial resolution than a multispectral image, because the broad spectral range allows for smaller detectors to be used while maintaining a high signal-to-noise ratio [7], [84], [87], [88]. In contrast, a multispectral image is one that contains more than one spectral channel. A simple example of a multispectral image is a colour image which contains three channels, corresponding to the red, green and blue wavelength channels of the electromagnetic spectrum [89]–[105].

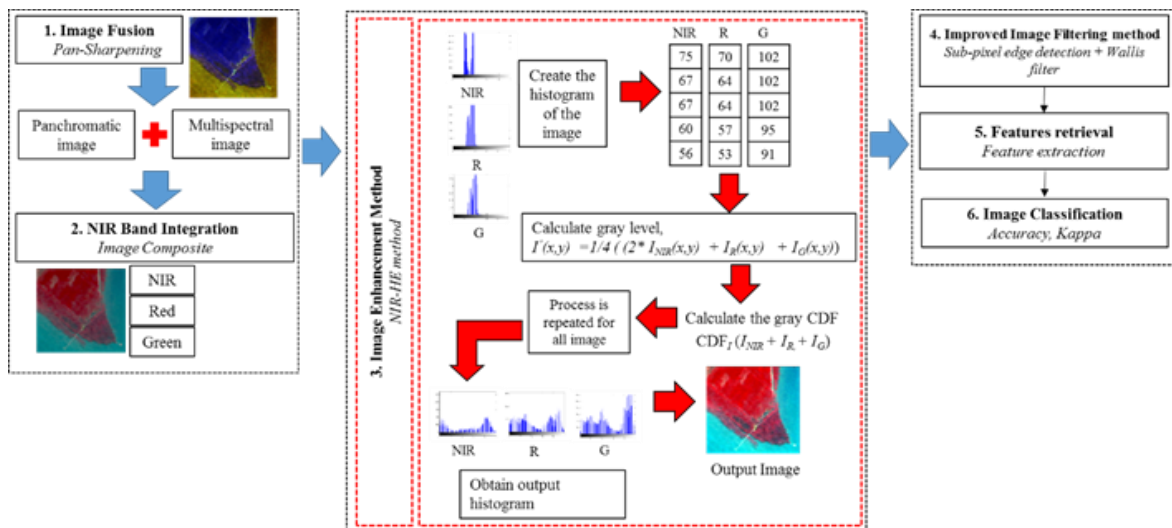

Figure 1. Proposed method

2.3. Integrating near-infrared channels

After the process, a multiband raster dataset (R, G, B) is produced. Then, the data image can choose either a single channel of data or can form a raster colour composite from multiple channels [84]. A combination of any three available channels within a dataset can create red, green, and blue (RGB) composites [106]–[113]. There are many possible schemes for producing an RGB composite or false colour composite images. However, each scheme has the ability to detect specific objects in an image. In this study, the false colour composites include the NIR channel, the green channel (G) and the red channel (R), as depicted in Figure 2. This integration of NIR channels is suitable for detecting vegetation and water bodies. There is a combination of the false colour composite used in detecting vegetation, with the red channel replaced in the NIR channel. The use of the NIR channel can help find a suitable local patch for air light-colour estimation [51].

Figure 2 shows a comparison of the histogram between an RGB image and false colour images. The histogram shows that the curve for an RGB image is within the range of 89 and 122, while the false colour image lies in the range between 25 and 200. This indicates that a pixel does not span a full range of RGB images. Moreover, the peak signal-to noise ratio (PSNR) value for the false colour image is shown to be slightly higher than that of the RGB image, due to the NIR channel’s integration onto the image [114]–[117].

This encourages the use of a false colour image throughout the study and the presence of an NIR channel, which makes the vegetation more vibrant and helps with edge detection and feature extraction [118]. Although the NIR channel helps improve vegetation and water body detection, the image needs to undergo image enhancements, in order to improve its image contrast and to improve its extracted edge detection.

Figure 2. Comparison histogram between (a) RGB image and (b) false colour

An image contains one or more colour channels, which defines the pixel location. The conversion of images is achieved through a colour map. The most common colour map is grayscale, which involves all shades of grey from black to white. Therefore, grayscale is particularly well suited to images with high intensity [119]–[122]. In addition to utilizing false colour, a map can better display the intensity in images [123]. Therefore, false colour images are mostly able to delineate and identify features for a human observer. An intensity scale known as the grayscale level, is in a digital image with an $m \times n$ array of values, for each pixel in a single sample, containing the image intensity information. In the 8 bits per sample pixel, up to 256 shades of gray are utilized.

The conversion of an RGB image to grayscale is a common approach used to retain information regarding brightness, and for discarding the values of hue and saturation. Each pixel is made up of three colours, including red, green and blue, which are used to describe intensity. In the RGB colour model, a colour image represents the intensity function presented in (1),

$$I = (I_R, I_G, I_B) \quad (1)$$

where I_R represents the intensity value of the pixel in the red channel, I_G represents the intensity value of the pixel in the green channel, and I_B represents the intensity value of the pixel in the blue channel.

The intensity of each colour channel is usually stored through the use of eight bits. Therefore, multispectral images store multiple values for each pixel, captured through the amount of light in different channels of the electromagnetic spectrum. The common multispectral images are RGB, which contain three channels that correspond to the R, G and B regions of the spectrum [39], [60], [84], [88], [94]. However, throughout the study, the false colour image is used, where the three channels correspond to the NIR, R and G regions. Converting a false colour image to a grayscale image involves mapping a three-channel image ($m=3$) to a single channel image ($n=1$). Therefore, a simple approach is considered, which involves averaging the three channel values, as presented in (2):

$$I = (I_{NIR} + I_R + I_G) / 3 \quad (2)$$

where I_{NIR} , I_R and I_G are the NIR, red and green channels of the input image, respectively.

However, the resulting image is not equally sensitive to all frequencies. Therefore, the channel average is tested by increasing the weight of the NIR channel. A significant improvement has been proposed by modifying the weight of the NIR channel. As a result, the gray levels for each channel are calculated and implemented, through using (3),

$$I' = ((r * I_{NIR}) + I_R + I_G) / t \quad (3)$$

where 'r' is the number of adding the NIR channel, 'NIR' is near-infrared, 'G' is green, 'R' is red, and 't' is a channel's total number.

The gray levels for each colour channel are calculated and implemented. In regards to false colour values, NIR is 102, R is 90, and G is 75. Then the image is tested to convert back to the false colour, through usage of a non-replicating transformation. This step ensures that the changes of the additional NIR channel serve to make the image darker or brighter, and also to ensure that the values are still within the range of 8-bit values. Therefore, the three separate colour channels are shown through settings, while the other colour channel is zero. For example, the NIR channel is visualized through (4).

$$I_{NIR} = I_{NIR}; I_R = 0; I_G = 0; \quad (4)$$

Therefore, the grayscale image is formed through utilising values from the NIR channel as (5).

$$I'_{NIR} = I_{NIR}; I'_{R} = I_{NIR}; I'_{G} = I_{NIR}; \quad (5)$$

From the results shown above, the average approach tends to increase the contrast. The formula manipulates the NIR channel weight, where the channel reflects more than other channels, given that the human visual system is more sensitive to the NIR channel than to the other channels. The advantages are that the division by four implements, due to an average of three channels and the addition of one channel weight, through multiples of two, by the weight of the NIR channel. Therefore, it may increase the NIR channel's weight. However, if the average used is more than two channels of the NIR channel, then the images will show greater contrast, and will cause image information loss and mixed pixels. As a result, the proposed method is suitable for a low contrast image of SPOT-5, whereby multiplying by two into the weight of NIR, will make the channel reflect the vegetation in the area of Tanjung Piai. In this case, the plants reflect NIR and green light, and absorb red. Therefore, the channel reflects more NIR than green, whereby plant-covered land appears to be deep red [30].

2.4. Image classification

The image classification process must be performed to identify and compare the accuracy by support vector machine (SVM) [33], [124]–[154]. In this study, a few polygon samples were created for training classes. These comprised of four classes, namely: vegetation, developed area, sea, and soil. These four features are selected not only because they are useful for shoreline edge detection, but also because these are essential for most urban planning applications which include development of areas, shoreline and vegetation extraction. Throughout the SVM method, the radial basis function (RBF) [126], [130], [146], [154] for kernel type and the threshold value of 0.70 are used for the classification process. Several trial-and-error run values using a threshold value in between the range of 0.10 and 0.70 are chosen in the initial experiments. These parameters obtained a higher accuracy performance level with more than 78% accuracy for all datasets.

3. RESULTS AND DISCUSSION

3.1. Analysis of the image enhancement method

The intensity of the contrast enhancement method has been observed through the enhanced images [155]–[165]. By using NIR, the red-colored pixels are produced, and it is more obvious when representing the healthy vegetation area. NIR helps penetrate further than the visible channel, due to its long wavelength. In this case, a darker image is assumed to be unable to reflect any solar energy, which indicates the histogram of a nearly zero digital number or brightness value. If the image presents surface reflectance, then the histogram of the visible channel shows a sharp increase in occurrence frequency at the lower-contrast level. Therefore, the pixel intensity histogram's leftwards skew indicates that the image is considered to have a dark level, with a low brightness level; and if the pixel intensity histogram is skewed to the right, then the image is considered to have a higher brightness level. Moreover, for the contrast level, if the pixel intensity histogram focuses on the center of the histogram, then the image will have lower contrast. On the other hand, if the pixel intensity histogram is distributed throughout the histogram range, the image will have a higher contrast level. This indicator was used to assess the image enhancement methods, using a variety of illuminations for optimal performance [28], [85], [86], [105], [140], [166].

The HE method was used to apply image enhancement individually to the gray-level images [167]–[176]. The NIR channel was integrated into the false color composite, combining the red and green channels, instead of the red, blue and green channels. The fusion criteria were based on the observation of the NIR channel images, which have higher contrast. Therefore, the NIR channel was used to refine the image's contrast. The HE method enhances the image by distributing the image brightness levels equally across the brightness scale [1], [11], [15], [21], [44], [53], [54], [72], [94], [119], [136], [140], [145], [150], [159], [168], [169], [172], [175]. Furthermore, the intensity of the contrast enhancement method is measured through the root mean square (RMS), where the higher the RMS value, the better the contrast image [22], [35], [48], [178]–[181]. As depicted in Table 1, the image enhancement methods for SPOT-5 images have been compared and ran to produce the best approach. The results of the histogram of colour pixel intensity distribution were analyzed. At this point the four methods produced three coloured pixels, including healthy vegetation areas indicated by red pixels, water areas indicated by blue pixels, and non-vegetated/developed areas indicated by white pixels.

The RMS values for the initial image have shown the lowest values, when compared to other methods. For the dark channel prior (DCP) method, the RMS value of scene three was 0.2441. Therefore, the image was not fully enhanced to its optimum level, after which it turned dark and the vegetation was harder to identify. The HE method performed an image contrast enhancement individually to the gray-level image. The HE method removed the surface reflectance in an image and enhanced the image contrast of the gray image. Therefore, the HE method produces better contrast, when compared to the DCP method, which produces an image with very high brightness, for all spectral channels. The HE method produced an RMS

value which is nearly equal to the proposed method, specifically 0.4192 for scene one, 0.4478 for scene two, and 0.4612 for scene three. However, the decorrelation stretch (DECORR) results are more suitable for density-based vegetation analysis, from which it is fit and able to distinguish more than one feature [182]- [194]. On the other hand, the proposed method enhanced the image by distributing its brightness levels together with the whole brightness scale [118], [193]. Therefore, the image has been improved to its optimum level, without losing details or causing shifts in colour. The RMS value for the proposed method shows the highest value, when compared to others. From this result, it can be concluded that the proposed method provides a higher image quality after image enhancement, and the image is surface reflectance-free.

Additionally, the peak signal-to-noise ratio (PSNR) is commonly used as a measure for image quality reconstruction. PSNR is the ratio between maximum possible power and corrupting noise which impacts an image's representation. On the contrary, the mean square error (MSE) represents the cumulative squared error between the enhanced image and the initial image. As a result, PSNR and MSE are interrelated. Where there is higher PSNR and lower MSE, a better contrast can be achieved [98], [171], [195]-[199]. Table 2 shows a comparison of PSNR and MSE results, when using the different methods. As seen in the Table 2, the proposed method has the highest PSNR when compared to the other methods. The use of the proposed method provides a greater contrast level, following the process of improving the low-contrast images. Therefore, the proposed method improves an image's contrast, when compared to other methods.

Table 1. Overall observation of RMS for Scene 1, Scene 2, Scene 3, Scene 4, and Scene 5

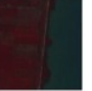

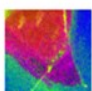

Method	Scene 1	Scene 2	Scene 3	Scene 4	Scene 5
Initial Image	 RMS: 0.1328	 RMS: 0.1523	 RMS: 0.1645	 RMS: 0.1741	 RMS: 0.1923
DCP	 RMS: 0.2022	 RMS: 0.2342	 RMS: 0.2960	 RMS: 0.2092	 RMS: 0.2534
HE	 RMS: 0.4192	 RMS: 0.4478	 RMS: 0.4612	 RMS: 0.3980	 RMS: 0.3592
DECORR	 RMS: 0.4157	 RMS: 0.4395	 RMS: 0.3264	 RMS: 0.4529	 RMS: 0.4425
Proposed Method	 RMS: 0.4974	 RMS: 0.4802	 RMS: 0.4744	 RMS: 0.4887	 RMS: 0.4724

Table 2. Comparison of PSNR and MSE result using a different method

		DCP	HE	DECORR	Proposed Method
PSNR	Scene 1	6.6143	12.6297	13.8147	18.1745
	Scene 2	10.1975	13.8147	14.6662	17.7938
	Scene 3	10.4347	14.8583	15.1158	18.0891
	Scene 4	11.3917	14.6568	13.3509	17.1538
	Scene 5	11.3284	13.8147	16.8198	18.2336
MSE	Scene 1	1.4179	3.5491	2.7016	1.0045
	Scene 2	6.2134	2.7016	2.0022	1.0807
	Scene 3	5.8832	2.1245	2.2205	1.0096
	Scene 4	4.7197	2.2254	3.0060	1.2523
	Scene 5	4.7889	2.7016	1.3524	1.2432

3.2. Analysis of feature signatures

Feature extraction allows for a more-accurate detection of features, as a result of the image's enhancements [15], [16], [39], [89], [143]-[145], [148]. The signature of feature classes could be distinguished from complex surface textures. Starting with image pre-processing through image

enhancement, a comprehensive method of features extraction has been implemented, creating a useful representation of the developed areas, vegetation, sea, and natural ground. Image enhancement is applied to the initial image, in order to produce an enhanced image for purposes of better clarity. Canny edge detection [7], [117], [160] was used to detect shorelines. Neither the Sobel, Prewitt nor Log methods were able to detect shore edges. According to the results, the proposed method demonstrated the best edge detection. Minimum and maximum thresholds were tested. However, the threshold at 0.07 produces the best results. In DCP, the result showed the lowest detection when compared to other methods. In Scene 2, the edge could not be detected due to the image's low contrast. For HE, the edge detection in Scene 2 showed that the edge could not be detected due to the image's brightness. The image consisted of misclassified pixels. However, the proposed method showed the best shoreline edge detection. All the edges were detected, and almost all surface reflectance was removed. An image's level of contrast affects the shoreline detection results. By using the Canny edge detector as the edge detector for shorelines in the surface reflectance images, a robust and very-high enhancement level was achieved.

The improvement of overall performance evaluation provided a corrected input image and produced better feature extraction, when compared to the initial image. The average accuracy of the initial image for all datasets was 76.39%, producing a low-quality contrast, due to the presence of surface reflectance. The DCP method for all datasets showed that the enhanced images produced a low quality of contrast with an accuracy that was about 89.78% and Kappa value was 0.86 as depicted in Table 3. As explained above, the enhanced image results of the HE method for all datasets, have produce more intensity values which achieved higher values for all datasets when compared with the DCP method. The average accuracy for all datasets is more than 80%, while the Kappa value is more than 0.83. For the DECORR, the enhanced image produced an 87.91% average accuracy for all datasets, while the mean of the Kappa value is 0.82. The accuracy and Kappa value achieved a higher value for all data sets, when compared with the other methods. This result showed that the proposed method produced better results when classified with the four class features. These included vegetation areas, developed areas, natural ground and soil. The average accuracy for the proposed method was found to be more than 85%, while the average of Kappa value was 0.88.

Table 3. Performance evaluation

		Accuracy (%)	Kappa			Accuracy (%)	Kappa
Scene 1	Initial Image	82.09	0.73	Scene 4	Initial Image	80.4	0.71
	DCP	89.78	0.86		DCP	83.14	0.8
	HE	91.06	0.88		HE	88.92	0.84
	DECORR	91.96	0.89		DECORR	92.12	0.88
	Proposed Method	92.75	0.9		Proposed Method	94.26	0.9

	HE	79.06	0.71		HE	87.46	0.83
	DECORR	84.09	0.78		DECORR	89.67	0.85
	Proposed Method	87.34	0.82		Proposed Method	92.12	0.88
Scene 3	Initial Image	78.5	0.69				
	DCP	86.99	0.81				
	HE	93.61	0.92				
	DECORR	86.57	0.8				
	Proposed Method	95.28	0.93				

4. CONCLUSION

In this study, an image enhancement method was proposed for low contrast images, formed due to the surface reflectance in SPOT-5 images. Therefore, a false colour composite, including the near-infrared (NIR), green and red channels, was chosen in order to increase the vegetation's contrast, as indicated in red. By using histogram equalization (HE), the image was adjusted in order to minimize the problem of darker spots or surface reflectance. The modification of the weight of the NIR channel made the vegetation reflect the NIR and green light. As a result, the NIR-HE method efficiently restored contrast for all datasets, producing a higher efficiency in edge detection, and achieving higher overall accuracy. Additionally, the root mean square (RMS) showed improved values. The accuracy and kappa value were obtained, in order to evaluate the maximum performance of the enhanced images. A success rate of more than 80% was achieved by using the proposed method, which proved that it could assist in high accuracy feature extraction.

ACKNOWLEDGEMENT

The authors gratefully acknowledge Universiti Teknologi MARA, Universiti Teknologi Malaysia, Universiti Kebangsaan Malaysia, Universiti Tun Hussein Onn and Universitas Ahmad Dahlan for supporting

Integrated NIR-HE based SPOT-5 image enhancement method for features ... (Farizuwana Akma Zulkifli)

this collaborative research in the present work, and also would like to thank Malaysian Remote Sensing Agency, which provided SPOT-5 data; and the Malaysian Government and Department of Survey and Mapping Malaysia (JUPEM) which provided topography and gazettes related to the Tanjung Piai area. Tanjung Piai Johor National Park staff provided useful information about the study site. This research was supported by the Myth Scholarship Scheme of the Ministry of Education Malaysia and the G-Heart scheme under the Gates Scholars Foundation. We also humbly acknowledge the FRGS/1/2020/ICT02/UTM/03/1 of FRGS grant funded by the Ministry of Education, Malaysia.
