ABSTRACT

Mobile applications that have data transactions between users require a database relational database management system (RDBMS) and RESTful API operating on the hosting service so that all users can access the data. Renting a hosting service is not cheap and creating a RESTful API takes plenty of time. As an alternative to hosting, a free version of the Cloud Firestore service gives full access rights to the database and has an application programming interface (API) to manage data or access data. However, the free version of Cloud Firestore has limitations in terms of storage capacity, read, write, and delete processes. Therefore, redesigning the process of the database was carried out into a low-cost version of the database model consisting of SQLite database and a low-cost version of the NoSQL database to overcome this problem. The goal is to reduce storage space usage and read, write, and delete processing on Cloud Firestore. The low-cost version of the database was tested with 6,030 data. The results obtained were savings of 47.27% storage usage, 83.08% write usage, 91.26% read process usage, and 83.19% delete process usage compared to the test results of the relational database model.

1. INTRODUCTION

Mobile applications are software that allows for mobility using mobile devices [1]. Mobile applications require data transactions to a relational database management system (RDBMS) via a RESTful application programming interface (API). A good application design must pay attention to database and API design so that optimally synchronization and integration can be carried out [2]. Efficiency in data processing is a challenge in application development, synchronization, integration, and concurrency, which is strongly influenced by processing activities (read, write, delete) [3], [4]. The goal is to produce a light/fast, and efficient application in database usage.

Database creation and Restful API are key in the data management process in an application [5]. Hosting services are required so all application users can access that data. Creating or renting a hosting service requires a fee that is not cheap unless you use the free version of the hosting service. Generally, the free version of the hosting service has several drawbacks; it does not provide full access rights to the database, and the server used has the potential to collapse [6].

Application programming interface (API) is a software interface used to facilitate the data exchange between two or more software applications [7]. The RESTful API implements the representational state transfer (REST) architecture to develop web services [8]. According to its function, RESTful APIs are often
called RESTful web services or REST web services. The REST architecture is run via hypertext transfer protocol (HTTP) and reads Extensible Markup Language (XML) or JavaScript Object Notation (JSON) files on web pages [9], [10]. The performance of REST web services has been studied to work efficiently both on local services and cloud servers, especially on mobile devices [11]. RESTful APIs can be built using various frameworks and programming languages, where the implementation process takes a long time depending on the data transaction processes that occur in an application [12].

The database becomes a data storage container in making mobile and web applications. The popular database technology used nowadays is the relational database management system (RDBMS). RDBMS has structured data in tables (rows and columns) and has relations between tables connected through primary and foreign keys [13]. RDBMS is the right choice when the type of data used is structured, but if the kind of data used is unstructured and requires high response and speed, the solution that can be used is the NoSQL database [14].

Not only SQL (NoSQL) is a database system that does not have to use structured query language (SQL) commands to perform the data manipulation process [15]. NoSQL, in its practice, is an efficient choice for simplicity, high work analytics, distributed scalability, and good adaptability, which certainly makes the process of storing and retrieving data easier [15]. Furthermore, the performance of query execution speed and the use of NoSQL database storage using MongoDB and Redis has been researched to be better than RDBMS with the percentage of processing time in the range of nanoseconds or milliseconds [16], [17]. RDBMS and NoSQL have their respective advantages based on the type of data that needs to be used. Combining SQL and NoSQL databases can produce more flexible and scalable database management because NoSQL can maximize large amounts of data processing more effectively [18].

Mobile application development includes various aspects in the implementation process, which will undoubtedly require no small expenditure if calculated in terms of costs [19]. Thus, the main focus of this research is minimizing the costs incurred in the application development process but still focusing on the efficiency of memory usage and data processing. One of the Firebase services, namely the free version of Cloud Firestore, can solve development costs, memory, and processing time efficiency problems.

Cloud Firestore is specifically reviewed as being able to be used for non-relational database implementations on mobile devices because it supports mobile client implementations while also can make integration into hosted databases relatively easier [20]. The Cloud Firestore service provides full access rights to the NoSQL database. It has an API to manage data to facilitate data storage, synchronization, and querying data on mobile applications [21]. Cloud Firestore uses a NoSQL database by storing data in collections containing a collection of documents containing data containing keys and values [22]. As a result, cloud Firestore has further complete and faster query features than realtime database services [23]. In addition to the advantages, the free version of Cloud Firestore also has limitations in storage capacity, read, write, and delete processes. Referring to the conditions provided by the Cloud Firestore website as of early November 2021, the storage capacity is only 1 GB, the read process is limited to 50,000 requests per day, the write process is limited to 20,000 requests per day, and the delete process is limited to 20,000 requests per day. If the process or storage area exceeds the usage limit that has been set, it will be charged according to the provisions of the Cloud Firestore service [24]. Thus, these problems can be overcome by redesigning the relational database model into a low-cost version of the database model.

The redesign process in this research uses a low-cost version of the NoSQL database and the SQLite database. SQLite database is used as a data storage medium that can operate locally [25]. The purpose of creating a low-cost version of the database model is to reduce the use of storage and processing (read, write and delete) on the Cloud Firestore service; thereby, it can save on data storage and processing costs. Denormalization will be involved in the migration process from RDBMS to NoSQL, followed by Optimization to get an optimal database design on Cloud Firestore [26]. The optimization process is carried out to eliminate redundancy and ambiguity in the data caused by the denormalization process. In principle, there is no specific method for denormalizing [27].

2. RESEARCH METHODS

The research was conducted by creating a low-cost version of the database model obtained from redesigning the relational database model (RDBMS). The research flow started from the creation of the SQLite database by determining data that can operate locally and not be used for data transactions between users. In contrast, other data or tables will be converted into a low-cost version of the NoSQL database model. These two databases will be the low-cost version of the database model. The research continued with the testing process of the relational database model and the low-cost version of the database on Cloud Firestore. Furthermore, the test results were analyzed and compared. The research flow in the form of a flowchart can see in Figure 1.
2.1. Relational database model

Relational database model is a database structure that has been normalized to a certain level and has a relationship between tables. Normalization is a technique for forming database structures so that most of the ambiguity and data redundancy can be eliminated [28]. The existence of non-constant data will undoubtedly affect the conceptual design of the designed database. Thus the task of normalization becomes very important in the database design process [29]. The relational database created contains five tables related to each other and has their respective functions. User’s favorite item data is stored in `tb_favorite`, user data is stored in `tb_user`, item data is stored in `tb_barang`, sales transaction data is stored in `tb_transaksi`, and every detail of the sales amount of goods will be stored in `tb_detail_transaksi`. The relational database design in Figure 2 will redesign to a low-cost version of the database model.

2.2. Redesign process for database optimization

The low-cost version of the database model uses two types of databases, namely SQLite databases to store data that can operate locally and are not used for data transactions between users and a low-cost version of the NoSQL database to be used on Cloud Firestore. SQLite database is an alternative Relational Database Management System that does not require an installation process since it is free and supported by many programming languages [30], [31]. SQLite can define as SQLite database used to store constant data on the final application, where the stored data is data that rarely changes or is static to avoid frequent interactions with the server [32]. Database redesign and optimization done on necessary tables as illustrated in Figure 3. `tb_favorite` is built on SQLite database because the data in the table can be processed and operated locally and not used for data transactions between users which is illustrated in Figure 3(a). `tb_transaksi` and
Data storage model in low-cost mobile applications

(I Made Sukarsa)

1131

tb_detail_transaksi are created in the NoSQL database by denormalizing the two tables that have foreign keys. Denormalization is conducted by modifying the table structure and ignoring (controlled) duplicate data to improve database performance [33]. Changes that occur in tb_transaksi after denormalization are the column replacement and addition. The id_user column is removed and replaced with the name, address, no_telp, and email columns. Additional columns are used to store detailed item information in tb_transaksi, namely kode_barang, nama_barang, jumlah and harga_jual as illustrated in Figure 3(b).

Optimization of the data structure is carried out to minimize ambiguity and redundancy in the data. Cloud Firestore has a data type in the form of an array that can be used to store data or transaction detail information without causing redundancy or ambiguity in the data. Fields used to store user information, and item information can be made into two different fields/columns with column names data_user and data_barang using array data types. Cloud Firestore also has a unique code that is automatically generated for each document to distinguish one document from another. Thus, it can delete the primary key in each table to optimize storage space. The low-cost version of the NoSQL database that will be implemented in Cloud Firestore includes three tables, namely tb_barang, tb_transaksi, and User. The data types of the low-cost version of the NoSQL database model have been adapted to the Cloud Firestore service, where the table names in the database model are used as collection names. Further, the column name will be used as the field name in the document where the data is stored, as illustrated in Figure 3(c).

2.3. Test data

The total data used for testing is 6,030 data. The total data consists of 10 item data, 10 user data, 10 favorite data, and 1000 transaction data, with each transaction having five types of goods. Item data will be inputted into the tb_barang collection, user data into the tb_user collection, favorite data into the tb_favorite collection, each of which will be stored in the relational database models and low-cost databases. Overall test data are presented in Tables 1, 2, 3 and 4, 5.

Transaction data will be input into the tb_transaksi collection in the relational database model and the low-cost version of the database. The storage process in the low-cost version of the database model is slightly different from the relational database. In the low-cost version of the database model, the user does not have to input id_user but instead inputs the name, address, no_telp, and email data based on the id_user. The transaction detail data that will be input into the tb_detail_transaksi collection in the relational database model includes the transaction id_transaksi, id_barang, jumlah and harga_jual barang fields. Meanwhile, in the low-cost version of the database, the data will be input into the tb_transaksi collection in the data_barang field, where the field contains kode_barang, nama_barang, jumlah and harga_jual.

![Figure 2. Relational database model](image-url)
Test is done by processing write data or inputting item data, user data, favorite data, transaction data, and transaction detail data. The test is continued by reading the transaction data along with user information and item details. Further, do the process of delete user data along with transaction data and details. Tables 1-5 are examples of data in the database structure to be tested.
Python is a programming language that is widely used for the analysis process because it is dynamic, object-oriented, and has good modularity [34]. Python also claims to be a language that combines capabilities, abilities, and an obvious code syntax and is equipped with automatic memory management [35], [36]. Python programming language also has advantages in developing a software product with a large and extensive data storage model in low-cost mobile applications (I Made Sukarsa)
library [37]. Test conducts for relational databases and a low-cost version in the Python programming language, as illustrated in Figure 4.

3. RESULTS AND DISCUSSION

3.1. Test results on the relational database model

The write data process is carried out by inputting user data, item data, favorite data, transaction data, and transaction detail data. The request used for the write data process is 6,030 requests. The use of storage space to accommodate all the data is 0.0011 GB. The read data process is carried out by reading/retrieving transaction data along with user and item information. The request used is 12,000 request read. Finally, the delete process is carried out by deleting user data along with transactions and transaction details. The request used is 601 request read and 601 request delete. The test results are shown in Table 6.
Data storage model in low-cost mobile applications (I Made Sukarsa)

3.2. Test results on the low-cost version of the database model

The write data process is carried out by inputting user data, item data, and transaction data. The request used is 1020 request write. The use of storage space to accommodate all the data is 0.00058 GB. The read data process is carried out by reading/retrieving transaction data along with user and item information. The request used is 1000 requests. The delete process is carried out by deleting user data along with transactions and transaction details. The request used is 101 request read and 101 request delete. The test results are shown in Table 7.

3.3. Test result analysis

The test results show that the use of storage, write processes, read processes, and delete processes in the low-cost version of the database model is smaller than the relational database model. The percentage value of comparison obtained in storage savings of 47.27%, write process of 83.08%, read process of 91.26%, and delete process of 83.19% compared to the relational database model. The percentages generated in Table 8 show that the low-cost version of the database with the Cloud Firestore implementation provides the advantage/savings compared to the relational database. The percentage value generated from the test results obtains using (1).

\[ P = \frac{(NVH - NN)}{NN} \times 100\% \]  \hspace{1cm} (1)

The variables description in (1) is as follows. NP is the percentage value wanted to find, and NVH is the value obtained from the test results on the low-cost version of the database model. Besides, NN is the value obtained from the test results on the relational database model. The test results are shown in Table 8.

The low cost version model in this study is not only suitable for use on transaction-based (OLTP) as in the example above, but also need to be applied to various services such as data exchange between applications and chatbots [38]-[40].

4. CONCLUSION

The process of redesigning the database to produce a low-cost version of the database model was obtained from breaking the relational database into SQLite and NoSQL databases, followed by a denormalization process. An optimization process will be carried out in the NoSQL database by changing the table structure and data type to become a low-cost version of the NoSQL database. The purpose of making

Data storage model in low-cost mobile applications (I Made Sukarsa)
this database model is to save the cost of storing and processing data transactions (write, read and delete) on Cloud Firestore. The database model test was carried out with 6,030 data consisting of 10 item data; 10 user data; 10 favorite data; 1,000 transaction data; and 5,000 transaction detail data. The test results obtained from the low-cost version of the database model were the storage usage of 0.00058GB, the write process usage of 1,020 requests, the read process usage of 1,101 requests, and the delete process usage of 101 requests. In addition, savings in storage usage of 47.27%, the write process usage of 83.08%, the read process usage of 91.26%, and the delete process usage of 83.19% compared to the test results of the relational database model. Furthermore, it is necessary to test database stress with various transactions both in terms of query variations, volume and user redundancy so that a critical point is obtained related to key matters in the application of design in non relational databases.
